**Draft, v1.09 – 12 July 2022. [See latest version HERE](#).**

## Abstract

This paper investigates potential mechanisms of social pressure leading to biased decisions. We revisit and extend [Garicano, Palacios-Huerta, and Prendergast \(2005\)](#) who found that football referees bias the length of stoppage time in favor of the home team. They argue that home bias arises in an attempt to satisfy the crowd in the stadium. Using exogenous variation in crowd size, along with a substantially finer and wider dataset, we propose a new mechanism – persuasion by host organizations. By including events with empty stadia, we show that the bias is uncorrelated with home crowd. Instead, we find that the bias mostly comes from favoring big and successful teams of the leagues. We find no evidence, however, of biased behaviour leading to better career outcomes for the football referees in Europe. This suggests that referees are not so much affected by social pressure from crowds or corruption but persuasion by the host team organization.

**Keywords:** social pressure, favoritism, persuasion, corruption, sport

**JEL-codes:** D71, Z20, C21

## 1 Introduction

Favoritism is the practice when a decision maker gives preferential treatment to one party at the expense of another, which is not warranted by the rightful determinants. It has broad consequences in a wide range of situations ranging from court cases to allocation of new stocks at IPOs. One source of favoritism is social pressure, the exertion of influence by a person or group. According to the *American Psychological Association*, channels of social pressure are persuasion (informational influence), calls for conformity (normative influence), and direct influence ([VandenBos, 2007](#)). Conformity is about agents' desire to conform to some expectations in hope of future rewards or in adherence to a social image ([Bursztyn and Jensen, 2017](#)). Persuasion,

where individuals or groups may try influence agent’s decision to adhere to their interest via persuasive communication ([DellaVigna and Gentzkow, 2010](#)). Direct influence or even corruption happens when an agent is offered or may reasonably expect future gains (or avoid losses) if adhering to a certain behaviour.

Despite its importance, empirical evidence about various channels is limited. As argued by [DellaVigna \(2009\)](#), it is difficult to distinguish social and psychological motives when it comes to observational data. Moreover, in line with [Bursztyn and Jensen \(2017\)](#), individuals may even care about how they are perceived by more than one reference groups, or may be influenced by more groups at once. As a possible solution, social scientists discovered sports data to gain insight about behavior of agents in a variety of settings driven by available data and some exogenous variation in rules. For instance, expectation of financial rewards were shown to lead to match rigging in Japanese Sumo wrestlers ([Duggan and Levitt, 2002](#)). Another prime example of such work is [Garicano et al. \(2005\)](#) who analyzed decisions by association football (soccer) referees who were shown to favor the home team. The paper has been frequently quoted being a rare case of identifying favoritism in the form of biased decision owing to influence of outside groups (fans in stadium).

Our paper revisits the football referee setting with a focus to better understand and tell apart the mechanism behind the referees’ biased decisions, and to offer evidence about the persuasion channel. To that end we compiled a novel and comprehensive dataset on European football games – events, referee decisions, referee career paths, and relied on an exogenous variation in the size of the outside groups owing to stadium closures due to the Covid pandemic in 2019 and 2020. The new data and the setup allowed us disentangling social pressure by fans and possible persuasion activities by host organizations to argue for the role of the latter in explaining biased decisions. Furthermore, persuasion is separated from possible direct pressure (or corruption) channel with an analysis of referee career paths shown to be unrelated to favoritism biases.

Our starting point is [Garicano et al. \(2005\)](#) who found that referees use discretionary power to systematically award more extra time to the home team when it stands to lose at the end of regular time, thus allowing more chances to catch up. The discretionary power allows referees to set the amount of extra time allowed at the end of the second half of the game to compensate for the time lost for a variety of events such as injuries. They argue that the mechanism behind this bias is that referees internalize in their decisions the preferences of the home team’s supporting crowd in the stadium. This mechanism is identified via variation in crowd size and composition: larger attendance generate greater bias, larger than usual capacity - a posited sign of higher share of visiting crowds yield lower bias. These findings are extended by [Dohmen \(2008\)](#) who suggested that distance to crowds – in stadia with running tracks – exacerbated the influence of crowds.

A key difficulty in such analyses is that the crowd size (and the type of stadium) is endogenous to the quality and wealth of host organization. Richer and hence, more successful teams tend to have larger and better stadium, making it hard to tell channels of social pressure apart. One will need more data and variation as well as better identification to identify the mechanism. To do that, we proceed in three steps.

First, we created a comprehensive novel, fine granularity dataset on 10 seasons (2011/12 to 2020/21) of the 5 most prestigious leagues in Europe: the English *Premier League*, the Spanish *La Liga*, the Italian *Serie A*, the German *Bundesliga 1*, and the French *Ligue 1*. We work with event-by-event data that records each action (such as passes, disciplinary action, penalties, injuries) along with a time stamp of that event. The nature and coverage of the data allows a precise estimate of the bias and the observation of great variation across leagues.

Comparing narrow margin standings after regular time, we find that referees on average add 13 seconds more extra time when the home team is losing compared to the case when the home team is winning. This is somewhat smaller than the 20 second bias that [Dohmen \(2008\)](#) found in the German Bundesliga for the 1992/93 to 2003/04 period, and substantially smaller than the 110 seconds [Garicano et al. \(2005\)](#) found for two Spanish seasons of 1994/95 and 1998/99.

Second, we use exogenous variation in crowd size – due to Covid related closures in 2020 and 2021 – to show that the bias is unchanged even without spectators. Thus, we confirm the existence of a referee bias, but find no evidence that the referee bias is driven by crowd size.

This result suggests that other form of influence must be in play: persuasion stemming from proximity to the host team and its organization. Here hospitality may play an important role: on match day, referees are surrounded by members of the host organization often spending the whole day at premises. Before, during, and after the match, the home team staff accounts for the safety and well-being of the referee, so he has some incentives to please them or at least not to make them hostile. Gifts from the home team are not uncommon either.<sup>1</sup>

If influence by team organizations matter, we shall expect greater bias when the influence is stronger. Indeed, we show that exposure to more successful (in terms of performance) teams is associated with a larger bias. Referees add more than twice as many seconds for the top 6 teams compared to the rest.<sup>2</sup> Note that our coverage of multiple leagues and seasons is necessary to test the power of the crowd effect during Covid.

Third, we investigated if persuasion may itself be confounded by direct pressure or corruption. While direct bribery is extremely unlikely, referees may expect professional rewards in the future when helping big teams. To refute this alternative hypothesis, we examined referees' careers in the prestigious European competitions where only the top teams play. If favoritism were driven by expectations of more work in these leagues, referees with higher bias would be picked more – in collusion with participating teams. We find no such evidence (neither in domestic leagues).

How can we reconcile our results with earlier ones? We suspect that earlier results on crowds may have been confounded by team characteristics that remain in play even in closed doors (or become even more salient): more successful teams have larger stadia, and less likely to have running tracks (no big team in Germany has tracks, while 9.8% of others have tracks), and a larger share of posited visitors is associated with better teams.

Taken together, we empirically measure a new channel of social pressure to prompt favoritism: persuasion by powerful groups, in a setting where it may be told apart from crowds or corrup-

---

<sup>1</sup>For anecdotal evidence, two examples are <https://www.theguardian.com/football/2015/mar/28/referees-football-match-day-routine-sport>, [https://en.as.com/en/2017/02/27/soccer/1488229755\\_283818.html](https://en.as.com/en/2017/02/27/soccer/1488229755_283818.html).

<sup>2</sup>The idea of top team bias in football has been shown in a different setting. Using Norwegian data and an expert panel, ([Erikstad and Johansen, 2020](#)) showed that the top 2 teams are more likely to get a penalty awarded.

tion. Instead of adherence to social pressure by crowds, we find evidence for adherence to host organizations, especially powerful ones. Interestingly, referees may yield to pressure by powerful organizations even if they don’t expect career gains. Note that our setting is very special: it is an extremely open and transparent situation. Thus, in more opaque settings, we expect a larger bias. This finding may have even greater external validity: think about independent advisors, accountants, consultants working for organizations – their advice may be biased towards their hosts, especially for large firms even in the lack of bribery.

The paper is broadly related to an emerging literature on using sports data to analyze human behavior.<sup>3</sup> More narrowly, the paper is related to earlier research, mostly in sport economics and psychology about referee bias for home teams for other outcomes such disciplinary action (yellow and red cards, free kicks, or penalties).<sup>4</sup> However, disciplinary decisions are always intertwined with the actions of the players making it difficult to empirically disentangle referee behavior from player behavior in these cases. Indeed several studies analyzed how the game may have changed during Covid.<sup>5</sup> The relative length of stoppage time allotted by the referee, however, does provide us with a measurable, isolated variable of referee behavior.

In what follows, we first describe the dataset we used in Section 2. Then we discuss our results in Section 3 in several steps: present evidence on home-team bias in referee decisions, show that it is not driven by the crowd in the stadium, speculate about possible channels and argue that an important factor is favoritism to successful teams. Finally, we also show the stability of our results over time and across countries. Section 4 concludes.

## 2 Data and empirical strategy

In this section, we first present our dataset, composed of several data tables from several sources. Second, we describe our core model and the variables we used.

### 2.1 Data sources

We use a sample of matches from 10 seasons (from 2011/12 to 2020/21) of the top 5 European leagues (England, France, Germany, Italy, Spain). In all leagues but Germany, there are 20 teams, 18 in Germany. Each team hosts every other team once in a season in its own stadium. This coverage would imply 18,260 games.<sup>6</sup> Our actual sample is slightly smaller. First, due to the Covid-19 outbreak, season 2019/20 of the French Ligue 1 finished prematurely, with only 279 out of 380 games played. Due to some deficiencies in our main data sources (see below), we lost another 41 games. Thus, our final sample consists of 18,118 games.

<sup>3</sup>Gauriot and Page (2019) also use football data to talk about quality perception biased by luck, while Parsons, Sulaeman, Yates, and Hamermesh (2011) looks at discrimination in US baseball.

<sup>4</sup>For referee’s home team bias, see e.g. Carmichael and Thomas (2005); Dawson and Dobson (2010), and for a review, Dohmen and Sauermann (2016); for more recent evidence on games during Covid see Bryson, Dolton, Reade, Schreyer, and Singleton (2021); Scoppa (2021); Reade, Schreyer, and Singleton (*forthcoming*).

<sup>5</sup>One example is Caselli, Falco, and Mattera (2022) who found evidence of African players doing better during closed doors.

<sup>6</sup> $10 \times 4 \times 20 \times 19 + 10 \times 1 \times 18 \times 17 = 18260$

Our dataset was created using several data sources.<sup>7</sup> First, we use an event level description of every game scraped from [whoscored.com](https://whoscored.com). Each event has a type and a timestamp (period, minute and second). Event types include: pass, ball recovery, throw-in, free-kick, yellow and red card, substitution, penalties, injury, shot, goal, and corner. In a typical game, there are around 750 events per team recorded before stoppage time, and around 30 events per team recorded during stoppage time, corresponding to around 17 events per minute, or an event being tracked every third or fourth second on average.

We aggregated this event data to game-half level by taking the sum of events flagged as goal, foul, substitution, yellow or red card, separately for each half of the game. To take into account the events taking place during stoppage time (in particular to be able to control for goals during stoppage time, as a crucial event that changes the outcome of the game), we aggregate events for regular time and stoppage time separately.

The second set of data is at the game level. It includes the venue of the game, attendance in the stadium, goals by home and away teams, referee name, date, and time. The third set of data concerns referees: their background such as age, as well as a history of experiences: number of games they refereed in domestic and European leagues. The data comes from [soccerway.com](https://soccerway.com) merged via referee names. Fourth, information about the stadium types come from [transfermarkt.com](https://transfermarkt.com) as well as wikipedia pages of clubs<sup>8</sup>.

The final set of data record various quality measures of teams used to create measures of influence at team level. This is a combination of three additional sources: betting odds, financial revenues, and squad values. Information on pre-match odds come from of the betting site [bet365.com](https://bet365.com) for home win, draw, and away win.<sup>9</sup> Finally, we collected data to estimate the squad value of each team for every season, using historical player valuations from [transfermarkt.com](https://transfermarkt.com).

## 2.2 Empirical strategy

In our empirical strategy we compare the stoppage time in games where the home team is winning by the smallest margin of one goal to the stoppage time in games where the away team is winning by one goal. Thus, our analysis includes the matches where the absolute goal difference at the end of regular time (90:00) is exactly one goal. Among these matches ( $N = 7021$  out of 18,118), we flag games where away team is winning before the stoppage time with a *Home losing* indicator variable. Our main outcome variable of interest, the length of stoppage time played, which is directly accessible from the event data based on the timestamp of the event indicating the end of the game, that is the minute and second of the referee’s final whistle. It may be slightly different than the stoppage time added, as referees may add seconds based on events like fouls and substitutions in the stoppage time.

To be able to make a causal claim, we need to exclude confounding factors as well as mechanisms of reverse causality. Most importantly, we have created a proxy measure for the amount

---

<sup>7</sup>Data and code will be made available.

<sup>8</sup>Close to fans is defined as not having a track or a sizable gap between the pitch and spectators. An example for a stadium with tracks is Hertha Berlin for a covered gap is West Ham’s London Stadium.

<sup>9</sup>The betting data was downloaded from [football-data.co.uk](https://football-data.co.uk), and was available for all but nine matches of our event data sample.

of wasted time by counting the time during which it is reasonable to assume that the ball was out of play. We did this by adding up the seconds passing between two consecutive events if the first event is a foul, a card, a ball picked up by the keeper, or a goal; or if the second event is a corner, a throw-in, or a substitution. Using this variable (*Wasted time*, measured in seconds) we are able to control for the effective playing time in the second half of the match and, as such, the best available approximation of the justifiable length of stoppage time.

We also control for the number of yellow or red cards, substitutions, fouls, and goals in the second half. These events are associated with the longest play stops. Although in theory our wasted time measure should capture all the effects of these variables, we include them in our specifications for two main reasons. First, instead of precisely calculating the seconds with the ball out of play, referees tend to use heuristics such as the number of these key events when they make their decisions on the extra time.<sup>10</sup> Second, these events are potentially confounding variables as they can be correlated with the goal difference as well, given that the playing style of the teams usually varies depending on winning or losing. Having said that, all our results are robust to leaving out some or all of these factors from the models.

During the examined 10-year period, a technological innovation has been introduced that may also affect the mechanisms underlying the bias of our interest. Both the use of VAR system and the compensation for the time lost may depend on whether the home or the away team is winning.

To control for this potential confounder, we generate a league-season level variable (*VAR*) indicating whether the technology was in use<sup>11</sup>.

A potential confounding effect may be that instead of favoring the home team, referees simply let the attacks started during the end of the stoppage time finish, even beyond the indicated length. It is a confounder because in general, the losing team is likely more offensive during stoppage time (because they need to score goal), and the away team is more likely to lose (due to the home advantage in general). To control for this possibility, we generate a variable by taking into account the passes of the losing team during stoppage time, and take the average distance of these passes from the team's own goal line. This variable (called *Losing offensiveness*) is measured in units of distance from the team's own goal line, on a scale from 0 to 100.

We also control for the round of the season for each match. This variable runs from 1 (the first match in the season for each team) to 38 (the last match in the season for each team in case of a league with 20 teams). The higher this number, the more stake there is in the game. It is reasonable to assume that the pattern of the matches changes as the season advances and by controlling for this factor, we rule out a potential confounder.

Since referees compensate for the wasted time at the end of both halves, we only consider events taking place in the second half of the game for each of these variables. The average stoppage time is around 4.5 minutes, ranging from 3 seconds to almost 18 minutes on the two

---

<sup>10</sup>See, for example, the following quote by former referee Dermot Gallagher: “(...)we’ve had this standardisation that we’re going to play 30 seconds per substitution, and for excessive goal celebrations we’re to play another 30 seconds – so it starts to tot up, and this is why we find the three or four minutes we have on average at most games.” – <https://playtheadvantage.com/2014/05/27/how-stoppage-time-is-determined/>

<sup>11</sup>VAR has been in operation since season 2017/18 in Germany and Italy, since season 2018/19 in France and Spain, and since season 2019/20 in England. See more in the Appendix 5.2

extremes. The home team wins slightly more games than the away team (56% compared to 44%), consistent with the well-documented general home advantage in sport (Jamieson, 2010). Our estimated wasted time in the second half varies between 9 minutes and more than 33 minutes. The average wasted time is 19 minutes (out of 45+4), which is equivalent to about 60% effective playing time, in line with the general findings of the sports press<sup>12</sup>.

For a broader review of descriptive statistics, see Table 6 in the Appendix.

### 3 Estimated models and results

In this section, we present results from our step-by-step empirical investigation. First, we confirm a referee bias supporting the home team. Second, we show that it is not driven by home crowds. Third, we explore variation in team influence and show that better teams enjoy a higher home-team bias. Finally we look at referee careers to see if stronger bias could help getting more prestigious work.

#### 3.1 Home-team bias is still there

Referees do seem to take into account the standing of the game when deciding on the length of the stoppage time.

As shown on Figure 1, the average stoppage time is the longer the tighter the match is. Since goals in stoppage time are rare events, matches with more than one goal difference at the end of the regular time are highly likely to be already settled, and in this case referees tend to blow the final whistle significantly earlier, serving the interest of both teams.<sup>13</sup>

The cleanest comparison to study referee bias comes from comparing a one-goal lead by either team. Thus, the pattern of interest for us is the 14 seconds gap between the two highlighted columns on Figure 1: the additional time seems to be extended if the home team is losing compared to when the home team is winning by a small margin.<sup>14</sup>

As a baseline model, we estimate the following model with OLS:

$$extra\_time_{h,a,s} = \beta home\_lose_{h,a,s} + \gamma controls_{h,a,s} + \delta_l + \eta_{hometeam_{h,s}} (+\theta_{referee_{h,a,s}}) + \epsilon_{h,a,s}, \quad (1)$$

where our unit of observation is a single game played between home team  $h$ , and away team  $a$  in season  $s$  in league  $l$ . As each team hosts every other team once in a season, the  $h, a$  dyad uniquely identifies a game in a season.

At each game, *extra\_time*, measured in seconds, is the length of playtime beyond the regular time (90:00 minutes). We run all our match-level regressions including only matches with a 1-goal difference at the end of regular time. That is, we compare games where the home team is

<sup>12</sup>See e.g. <https://football-observatory.com/IMG/pdf/mr64en.pdf>.

<sup>13</sup>Because a draw (that is, zero goal difference) may be useful for one or the other team depending on many aspects of the game and the season, we do not base our analysis on drawing games.

<sup>14</sup>For more details about stoppage time, see Section 5.2 in the Appendix.

Figure 1: Average stoppage time by goal difference at 90:00

losing by one goal ( $home\_lose = 1$ ) with games where the home team is winning by one goal ( $home\_lose=0$ ).

We use a rich set of control variables ( $controls_{h,a,s}$ ). Along with our wasted time measure (the most precise estimation determining the justifiable length of stoppage time), we also include the number of goals, substitutions, cards, and fouls in the second half – factors that influence referees’ stoppage time decision as rules of thumb. We separately control for the number of goals in extra time, to take into account the possibility that this can change the structure of the extra stoppage time. We also control for *Losing offensiveness*, and add a binary variable that captures whether VAR was in operation in the given match. In some specifications, we include three sets of fixed effects: league fixed effects  $\delta_{league}$ , home team fixed effects  $\eta_{hometeam}$ , and referee fixed effects  $\theta_{referee}$ .

We find that referees tend to help the home team by letting the game play longer by around 13 seconds, on average. Table 1 reports the result of several model specifications, each using a different set of control variables and fixed effects. Each of these estimations finds a robust, 11.1 to 14.3 second bias.

We believe that  $Controls_{h,a,s}$  variables<sup>15</sup> (events, wasted time, VAR, losing offensiveness), home team and league fixed effects  $\delta_{league}$  and  $\eta_{hometeam}$  are confounding variables.

Referee fixed effects  $\theta_{referee}$  may be part of the mechanism through which bias works. Differences in the habits of referees regarding the extra time length as well as their attitude towards home and away teams can be captured by referee fixed effects. It cannot be excluded, however, that allocation of referees is not random, and certain types of games are given to referees with

<sup>15</sup>See Table 7 in Appendix for how these variables affect stoppage time.

Table 1: Regressions indicating home-team bias

	(1)	(2)	(3)	(4)	(5)
	Extra secs	Extra secs	Extra secs	Extra secs	Extra secs
Home lose	14.28*** (2.24)	13.38*** (2.04)	11.10*** (1.79)	12.80*** (1.79)	12.72*** (1.76)
Controls	No	Yes	Yes	Yes	Yes
League FE	No	No	Yes	Yes	Yes
Home team FE	No	No	No	Yes	Yes
Referee FE	No	No	No	No	Yes
Observations	7021	7021	7021	7021	7001
$R^2$	0.01	0.28	0.38	0.41	0.44

*Note:* Standard errors clustered at home team level. Controls include time with ball out of play, number of cards, substitutions, fouls, goals, goals in stoppage time, round of season, whether VAR was used, and losing offensiveness (average distance of the passes of the losing team from opponent goal in the stoppage time). Note that 20 referees worked on a single game only and hence, the last column has 20 observations less.

habits of allotting longer or shorter stoppage time. Thus our preferred specification is Model (4). As Table 1 suggests, however, these decisions do not affect our conclusion. In our subsequent analysis, we specify our models without referee fixed effects, though all our results are robust to including them.

### 3.2 Home-team bias not driven by the crowd

Garicano et al. (2005) argued that the supporting crowd at the stadium makes referees feel a pressure to help the home team. Identification came from comparing attendance to capacity rates across games, arguing that higher attendance is likely attributed to more fans of the away team and hence, a lower pressure. Others in the literature also assume that the source of the home-team bias is fans cheering for the home team.

Our key contribution is to use stadium closures as a natural experiment to disentangle the mechanism behind the home-team bias in referees' stoppage time decisions. In particular, we use the Covid-19 pandemic as an exogenous variation in stadium attendance to assess whether the bias can be attributed to fans present in the stadium.

Due to the Covid-19 outbreak in Europe in Spring 2020, practically every football league was suspended as of the second weekend of March. The leagues resumed around May-June, with matches played behind closed doors. In Spring 2021, partial opening meant that stadiums were filled to 10-30% of capacity. We created two indicator variables,  $Closed = 1$  when attendance is zero, and  $Covid = 1$  that also include very low attendance games in 2021. As Table 2 shows, though, the difference between these two categories is small, since only a very limited number of matches have been played with attendance since the Covid outbreak in our sample.

Table 2: Attendance of matches during Covid

Season	N	N closed	N open	Mean atten- dance	Max atten- dance
England 19/20	380	92	0		
England 20/21	380	346	34	12.3	25.9
France 19/20	279	1	0		
France 20/21	378	316	62	15.1	33.8
Germany 19/20	306	83	0		
Germany 20/21	306	269	37	10.4	20.5
Italy 19/20	380	132	0		
Italy 20/21	380	379	1	1.3	1.3
Spain 19/20	380	111	0		
Spain 20/21	378	373	5	11.9	21.7

*Note:* The last two columns indicate the mean and maximum, respectively, of attendance-to-capacity percentage among games where reported attendance was greater than zero.

The natural experiment, induced by the outbreak of the Covid-19 pandemic, allows us to test the hypothesis, articulated by [Garicano et al. \(2005\)](#), among others, that the referee bias favoring the home team is the consequence of the social pressure exerted by the supporters of the home team in the stadium. In particular, in Table 3 we estimate

$$\begin{aligned}
Extra\ time_{h,a,s} = & \beta_1 Home\ lose_{h,a,s} + \beta_2 T_{h,a,s} + \beta_3 Home\ lose_{h,a,s} \times T_{h,a,s} \\
& + \gamma Controls_{h,a,s} + \delta_{league} + \eta_{hometeam_{h,s}} + \epsilon_{h,a,s},
\end{aligned} \tag{2}$$

where our treatment indicator  $T_{h,a,s}$  flags only closed matches in Models (2) and (3), and all Covid matches (including those with restricted number of fans) in Models (4) and (5). In both models, all control variables are also interacted with the *Covid* or *Closed* dummy to capture that referees may take different amount of time to make decisions depending on broad circumstances such as closed stadium.

We find that eliminating crowd from the stadium has no effect on referee bias. The estimated interaction terms are zero in all specifications: with and without home team FE, and using all Covid games or fully closed ones.

This result suggests that while referees as biased as before in supporting the home team when it is losing, their actions cannot be driven by crowd size. Even in the extreme and exogenous case of closed games, the home-team bias remains as it was before. Thus, crowds cannot be the main driver.<sup>16</sup>

<sup>16</sup>Our results refer to the 2011-2021 period. Note that our estimated coefficient for Germany is 16 seconds, close to what was measured earlier by [Dohmen \(2008\)](#) but are a magnitude smaller than the one in [Garicano et al. \(2005\)](#). In lack of available data from the period it is hard to make a direct comparison. We estimated their core model in their Table 2, column 4, and found a similar estimate to our favored specification. It is possible that referee behavior in the nineties in Spain had less oversight indeed.

Table 3: Regressions indicating no crowd effect

	(1)	(2)	(3)	(4)	(5)
	Extra secs	Extra secs	Extra secs	Extra secs	Extra secs
Home lose	13.10*** (1.77)	11.60*** (1.76)	13.22*** (1.77)	11.57*** (1.77)	13.17*** (1.77)

Observations	6151	7021	7021	7021	7021

*Note:* Standard errors clustered at home team level. Controls include time with ball out of play, number of cards, substitutions, fouls, goals, goals in stoppage time, round of season, whether VAR was used, and the average distance of the passes of the losing team from opponent goal in the extra time. All these variables are also interacted with the *Covid* or *Closed* dummy.

This results deviates from established wisdom on the role of crowds generating social pressure. It is, however, very robust to specifications and also across leagues – see Figure 4 in Section 5.6 below.

### 3.3 The home-team bias driven by influential teams

In this section we investigate if team influence is indeed correlated with the size of the home-team bias. Influence is the capacity to exert social pressure. Team influence is hard to measure directly. It may stem from amenities, wealth of the club, quality of the team (squad, management, the whole organization) as shown by performance in the season. In the case of football teams, influence and success are very close concepts.

In this context, we think about team influence as a function of two concepts: wealth and quality. Wealth could be measured as the value of current players as well as wealth in a broader sense taking into account past achievements and brand value. Quality could be measured by the total points or the ranking in the league, pre-game odds or Elo rating, a longer run measure of teams' strength. Our baseline specification will use league table ranking as it captures the influence of teams in an easy way. Ranking is defined as the end-of-season ranking of the team in the league table, the lower the better (1 is the winner, 18 or 20 is the last team). The final ranking in a year is close to expected average ranking throughout the year.<sup>17</sup> Nevertheless, all

<sup>17</sup>The advantage of this measure is that it is what teams care about, an easy metric to interpret, can be compared easily across leagues. Unlike past performance and all teams have a value for it in all seasons.

Figure 2: Heterogeneity of home-team bias by team ranking

*Note:* Local polynomial smoothing and a 95% confidence interval. Bias measured in seconds, rank between 1 (best) and 20 (worst); 1-18 for Germany. Predicted extra time is the residual from a regression of extra time on football rule controls (time with ball out of play, number of cards, substitutions, fouls, goals, goals in stoppage time, round of season, whether VAR was used, losing offensiveness (as average distance of the passes of the losing team from opponent goal in the stoppage time) all interacted with *Closed* dummy).

of these wealth and quality measures are highly correlated with a correlation coefficient between 57% and 92%.

Influence is likely to be non-linear as it also based on the ability to play in the two pan-European competitions: typically the top 6 teams will play in either the UEFA Champions League or in the UEFA Europa League. Thus, we will also consider a binary variable to measure influence being inside or outside the top 6 teams per league.

To better understand the relationship between extra time and ranking, we first estimate a model with only the football rule controls (such as time with ball out of play, number of cards, substitutions), as described in Section 3.1. Then, we compute the difference between predicted and actual stoppage time. This bias from equation 3 is the measure of the unexplained difference.

$$Bias = Extra\_time_{h,a,s} - \hat{\gamma}Controls_{h,a,s} + \hat{\delta}_{league} + \hat{\eta}_{hometeam_{h,s}} \quad (3)$$

In the second step, using local polynomial smoothing regressions, we plot this bias against heterogeneity by the ranking of the home team. In Figure 2a, we see a fairly strong pattern with better teams enjoying a greater home-team bias. This is especially true for the top few teams. In Figure 2b, we see a similar pattern with the difference plotted against bias: when the top teams play against lower ranked ones, the gap is 30 seconds, but it goes down to 0 when minnows play at home versus against the top teams.<sup>18</sup>

We estimate this heterogeneity in two ways. First, we consider variation by the home team influence, with  $\beta_3$  measuring the heterogeneity in home-team bias. The *Home\_ranking<sub>h,s</sub>* variable may be estimated in a linear form or with a binary indicator variable (influential teams defined as the top 6 teams in each league).

<sup>18</sup>Alternatively, confounders may be partialled out of rank as well, only to give very similar graph.

$$\begin{aligned}
Extra\_time_{h,a,s} = & \beta_1 Home\_lose_{h,a,s} \\
& + \beta_2 Home\_ranking_{h,s} + \beta_3 Home\_lose_{h,a,s} \times Home\_ranking_{h,s} \\
& + \gamma Controls_{h,a,s} + \delta_{league} + \eta_{hometeam_{h,s}} + \epsilon_{h,a,s},
\end{aligned} \tag{4}$$

An alternative model uses the difference between home and away team, with  $\beta_3$  measuring the heterogeneity in home-team bias in terms of the difference between ranking. The  $Home\_ranking\_difference_{h,s}$  variable may be estimated in a linear form or with a binary variable, where the difference is defined as a gap greater than -10 (defined in terms of season-end league position).

$$\begin{aligned}
Extra\_time_{h,a,s} = & \beta_1 Home\_lose_{h,a,s} \\
& + \beta_2 Home\_ranking\_difference_{h,a,s} \\
& + \beta_3 Home\_lose_{h,a,s} \times Home\_ranking\_difference_{h,a,s} \\
& + \gamma Controls_{h,a,s} + \delta_{league} + \eta_{hometeam_{h,s}} + \epsilon_{h,a,s},
\end{aligned} \tag{5}$$

The results of both models are presented in Table 4. The simplest setup is considering the binary Top 6 ranked team indicator in column (1) of Table 4. Influential (top-ranked) teams enjoy a home-team bias that is more than twice the one for non-influential ones (10.23 vs 22.98 seconds).

Looking at the home team's ranking in a linear way in Column (2), we see 19.8 seconds for the number 1 team ( $20.48 - 1 \times 0.67$ ), and this gain is reduced by 0.67 seconds per rank. For the last team in the league, the home-team bias shrinks to 7.1 seconds ( $20.48 - 20 \times 0.67$ ).

Next, we add the difference between teams in terms of ranking from the perspective of the home team. The difference thus ranges between 19 (when the lowest ranked team plays at home against the best one) and -19 (when the top team hosts the bottom team).

In the binary setting, we once again find that when there is a sizeable gap in favor of the home team, the bias is twice the size compared to non such difference (12.05 vs 27.70 seconds). In the linear model, for equal teams the bias is 14 seconds and the slope is -0.84. In case of a difference of 19 ranks, the estimated bias is -2 seconds,  $13.94 - 0.84 \times 19$ , and in the other direction, it is 29.9 seconds.

These results suggest that referees have a home-team bias that is substantially higher for more influential (top-ranked) teams, especially when they play against less influential (low-ranked) ones.

Note that as the different aspects of success (such as points and ranking, financial power, size of supporting base, clout outside the league, etc.) in football are strongly correlated, we cannot empirically dissect whether the effect comes, in general, through money or popularity. Indeed, we find that our results are qualitatively robust to the two alternative measures (such as odds difference and squad value difference) as well.<sup>19</sup>

---

<sup>19</sup>See the coefficient table for these in Appendix (Tables ?? and ??).

Table 4: Regressions indicating home-team bias heterogeneity

	(1) Extra secs	(2) Extra secs	(3) Extra secs	(4) Extra secs	(4) Covid
Home lose	10.23*** (1.84)	20.48*** (4.41)	12.05*** (1.76)	13.94*** (1.86)	9.94*** ( )

Home team FE	Yes	Yes	Yes	Yes	Yes
$R^2$	0.41	0.41	0.41	0.42	0.34
Observations	7021	7021	7021	7021	1230

*Note:* Standard errors clustered at home team level. Controls include time with ball out of play, number of cards, substitutions, fouls, goals, goals in stoppage time, round of season, whether VAR was used, and the average distance of the passes of the losing team from opponent goal in the extra time. All these variables are also interacted with the *Closed* dummy.

Finally we can look at how the difference between the influential (top ranked) team and others may have changed during closed games. In column (5), we repeated column (1) but only for the covid period and found that in these games, influential teams are twice as much as before when in need. This points to a situation where the host organizations play a very important role (protection against Covid ), hence seem to have an even greater influence on referees. This is another source of evidence on pressure coming from the organizations.

To summarize, we find that influential (top-ranked) teams benefit substantially more from referee decisions. The result is stable over time, and if anything, the gap in benefit has further increased in closed games. When playing at home the top influential teams seem to create an environment that makes referees more inclined to help. It is the influence of the host team organization and not the crowd size that determines referee behavior.

This finding is important because it may explain earlier evidence. Team influence is correlated with many observable characteristics: stadium attendance and capacity, even the type of stadium teams have. For instance, home team, league, and season, along with an indicator of a top away team explain more than 75% of the variation in the attendance rate across all matches in all samples; see Table 12 in the Appendix. Similarly for running tracks, the top 6 teams in Germany

have no tracks in their stadium but of the rest do. Thus, the hypothesized effect can be more reliably identified on the extensive rather than on the intensive margin, in particular by focusing on how the bias changed when no fans were present in the stadiums at all.

### 3.4 Is there corruption? Referee career in Europe

Finally, we investigate if career concerns may motivate referees to help influential teams. The main question we address here is whether more biased referees are more likely to get work at the UEFA Champions League and in the UEFA Europa League games. Working in these European games are a pinnacle of both player and referee careers.

To analyze careers, we aggregated game information into an unbalanced panel of referees ( $r = 1 \dots 233$ ) and seasons ( $s = 2011 - 12 \dots 2020 - 21$ ). This panel ( $N = 1148$ ) covers 1-10 seasons for 233 referees. On average we observe a referee for 4.9 seasons in their national leagues work on 70 games, 33 of which would have a one goal difference after 90 minutes. For each referee and season, we define average referee bias in two ways. First,  $Bias_{r,s}$  is the average seasonal ( $s$ ) deviation from the predicted stoppage time for referee  $r$  when the home team is losing minus the average deviation when the home team is winning, based on our model (3). Second, the  $bias\_influential_{i,s}$  is the same difference but for only for influential (top 6 ranked) teams. Both measured are calculated over two years.

This new dataset is referee \* season level, but only contains referees who had both at least one 0:1 and 1:0 result after regular time result in a season. Dropping extreme values for the bias (beyond 2 minutes), we are left with 196 referees and  $N = 907$  referee\*season observations. This dataset was merged with information on referee work during the same period in the Champions League and in the Europa League. We also have information some key personal features of the referees (age), as well as the past of referees in our sample (number of games refereed in previous years).

To analyze the relationship between European career and bias, we estimate both a cross-section and a within referee (fixed effects) model to see if referees with a great bias referee more and if referees when

First, we estimate a cross-sectional linear probability regression, with the dependent variable,  $euro_{r,s}$  is one when referee  $r$  worked at least a single game at either competitions in season  $s$  and zero otherwise.

Experience is a key potential confounder in this model, and hence we restrict the sample for the 4th national league season for each referee. We also add referee age, and number of national league games in the two years before the current season.

$$Pr(euro_{r,s} = 1) = \alpha + \beta_1 bias_{r,(s-1,s-2)} + \beta_2 experience_{r,(s-1,s-2)} + \gamma_1 age_{r,s} + \epsilon_{r,s}, \quad (6)$$

Results are presented in Table 5. In column (1) of Table 5, we find that referees who work in more games are slightly more likely to work in the UEFA competitions, but average bias does not matter at all. Results are robust to alternative specifications, such different season for a referee.

Table 5: Referee bias and UEFA jobs [TO REPLACE]

	(1) CL+EL	(2) CL	(3) CL+EL	(4) CL+EL	(5) CL+EL
	binary	binary	count	binary	binary
Bias	0.000288 (0.000549)	0.000333 (0.000371)	0.00144 (0.00195)	0.000266 (0.000323)	2.86e-05 (0.000689)
Matches in league	0.0119** (0.00518)	0.00457 (0.00528)	0.0471 (0.0290)	0.00404 (0.00460)	0.00593 (0.00644)
Constant	-0.0861 (0.195)	0.0131 (0.194)	-0.530 (1.030)	0.198 (0.196)	0.312 (0.308)
Observations	104	104	104	558	71
R-squared	0.163	0.079	0.149	0.740	0.256

*Note:* Linear probability model regressions (column 1,2,3,5), with referee fixed effects in column 4. Robust standard errors (col 1,2,3,5), referee level clustered standard errors (col 4). Predicted bias is based on 3. In columns 1-4, the bias is the difference in the average residual when the home team is losing vs winning. In column 5, it is the difference between influential and non-influential teams when losing at home.

Second, instead of a cross section, we look at within referees cases: does a referee get more opportunities in seasons when he is more biased than his average? We now add the referee fixed effects,  $\Theta_r$  to the same model, and estimate it for all seasons (linear age is dropped to to season dummies).

$$Pr(euro_{r,s} = 1) = \alpha_s + \beta_1 bias_{r,(s-1,s-2)} + \beta_2 experience_{r,(s-1,s-2)} + \Theta_r + \epsilon_{r,s}, \quad (7)$$

Once again, we find no correlation as shown in Column (2) of Table 5. Both of these results are robust to the count of games (column (3)), or the count of games in UEFA Champions League only (Column (4)).

Finally, we repeat both regressions with a different bias definition,  $bias_{influence_{r,s}}$ . There are much fewer observations here, so we only estimate a pooled OLS with season dummies as well as a variable counting the number of season a referee worked in the domestic league. As shown in Table 5 column (5), once again, we find no correlation.

Thus, we see no correlation between any type of referee bias and the likelihood of the referee working in the UEFA competitions – a key metric of career success in European football.

## 4 Discussion

In this paper, we extended and revisited earlier evidence of favoritism under social pressure, measured by home-team favoring bias among European football referees. Using extensive data consisting of more than 7 thousand football matches from 10 seasons of the 5 top European leagues, we find that referees support the home team by allowing the game to last longer if they are losing. Importantly, the bias is not due to crowds as it exists even in the absence of home

fans, but it is larger when favors an influential (top-ranked) teams, and is especially large when an influential team is losing at home to a minnow. We showed that referee bias is, however, uncorrelated with career benefits.

Why do referees support successful teams? After ruling out direct social pressure or corruption, we are left with some more nuanced explanations. It may be the consequence of an unconscious bias driven by a persuasive home team organization. People are often uncertain about their decisions and this is when this bias kicks in. Maybe under an influence or s they are more willing to err on the side of persuasive group. For instance, risk aversion happens as referees make errors including that they do not compensate enough for wasted time. Such an error may get unpunished if it hurts a small team but may get massive coverage in the media when a top team suffers. The more successful (wealthy, star-studded) the host, the greater this influence.

[One closing para on why this is important]

## 5 Appendix

### 5.1 Descriptive statistics

Table 6: Summary statistics

	Mean	SD	Median	Min	Max	N
Stoppage time (sec)	260.03	77.42	248	3	1065	7021

Rank difference (H-A)	0.40	7.95	1	-19	19	7021
Home team value (m EUR)	8.43	9.58	4.81	0.81	64.14	7021
Away team value (m EUR)	9.10	10.22	5.07	0.81	64.14	7021
Value difference (H-A)	-0.67	12.73	-0.17	-61.60	61.60	7021
VAR (0/1)	0.32	0.47	0	0	1	7021

*Note:* The sample consists of games with a one goal difference at 90:00, from seasons between 2011/12 and 2020/21 of the top 5 European football leagues. All variables concern events happening in the second half of the games only (where this is relevant). See Section 2.2 for a detailed description of the variables.

### 5.2 Football rules: stoppage time, VAR

The length of the stoppage time is very strictly defined in professional football. According to Point 7.3 of *Laws of the Game*, the official rules of football maintained by the International Football Association Board, the extra time at the end of both halves should compensate for the time lost through substitutions, injuries, wasting time, disciplinary sanctions, cooling breaks, VAR checks, and any other cause such as goal celebrations. Towards the end of the regular play time, the fourth official indicates the minimum additional time. The actual extra time can be increased but not reduced by the referee.

The referee decision is driven by a set of detailed rules regarding which events may generate an extension. The exact length is, however, determined by the referee.

Figure 3 plots the kernel density estimate of stoppage time distribution for these two outcomes separately (Panel 3b), along with that for the full sample (Panel 3a). We can observe spikes around each minute: the largest at 3 minutes in the full sample. We can also see that as we move towards longer stoppage time, home losing matches are dominating starting the fifth

Figure 3: Distribution of additional time

additional minute. A Kolmogorov-Smirnov test also confirms the statistical significance of the difference between the two distributions.

The Video Assistant Referee (VAR) system, aims to minimize human errors and their influence on match outcomes. Video replays of key events of the game (such as goals, penalties and red card fouls) are reviewed by an official who communicates with the referee on the pitch. If a potential referee mistake is identified, the game is interrupted for an on-field review of the situation, often lasting several minutes. Time spent reviewing decisions is intended to be compensated for by adding more stoppage time.

### 5.3 Covid and closures

Due to the Covid-19 outbreak in Europe in Spring 2020, practically every football league was suspended as of the second weekend of March. The last round before suspension was played behind closed doors in Italy on the 8th and 9th of March, as well as the last game in our sample, played on the 11th of March in Germany. The remaining games of the 19/20 season were played, with a more intensive schedule, starting as of the 16th of May in Germany, the 11th of June in Spain, the 17th of June in England, and as of the 21st of June in England. Each of these games was played behind closed doors, with no supporters allowed to enter the stadium. In France, the remaining games of the 19/20 season were not played.

Season 20/21 started in August 2020 in France and in September 2020 for the rest of the leagues. The vast majority of the games were played behind closed doors. Depending on the severity of the Covid situation, some leagues allowed a restricted number of supporters to be present in the stadium for short periods throughout the season. This was the case for France between August and October 2020; for England and Germany between September and October 2020, and in May 2021; for Italy and Spain in May 2021. As Table 2 shows, this partial opening meant that the stadiums were filled to 10-15% of capacity on average. No match was played with full capacity of fans during season 20/21 – the highest attendance-to capacity ratio in our sample is 34%.

## 5.4 Data cleaning

For a few games, the source of our event data contains either no information or obviously erroneous information, such as extremely few events recorded. As we cannot construct the measures of interest for these matches, our analysis excludes them.

We excluded a game with more than 33 minutes of wasted time corresponding to a severe head injury of the goalkeeper, which involves on-field medical care and, thus, a long period of play stop.

Our *Losing offensiveness* measure is not observed for 7 games in our sample, implying that on these games the losing team did not have a single pass in the stoppage time. Thus, we impute a value of 0 for these in our analysis.

## 5.5 Alternative model estimations

Table 7 presents the models of Table 1 with indicating how each of our control variables is related to the length of stoppage time. We see that all factors have a strongly significant effect on the outcome variable.

Table 8 replicates the main models of [Garicano et al. \(2005\)](#). See the specific table and column reference in the Table.

Tables 9, 11 and 10 show the regressions visualized on Figure 4.

Table 12 argues that the attendance to capacity ratio is to a large extent explained by the home and away teams themselves, along by the league and the season. As such, no proper inference can be made on the basis of the variation of this measure.

## 5.6 Persistent results across leagues and time

Different countries and leagues may have different customs and regulations. Thus, we might see heterogeneity for any of our results, or find that they are driven by peculiarities in a single country.

To illustrate how heterogeneous our main findings are across countries, we run regressions of Model (4) of Table 3 and Model (1) of Table 4 for each league separately (without league fixed effects). The estimated coefficients are presented in the Appendix Tables 9, and 10.

We find that all main results are highly robust across leagues. First, the home-team bias is very similar, ranging between 9.2 and 15.8 seconds (not statistically different from each other). Second, we see that during closed games, all leagues experienced a small change only, with point estimates ranging between -7 and +5 seconds, neither being statistically different from zero. Third, in terms of the moderator variable of influential teams, the interaction term of the home lose indicator and the indicator for the top 6 teams is rather stable across leagues, ranging between 10-17 seconds (neither is statistically different). Note, however, that broken down by leagues, this result lacks statistical power, and the results are not significant. This is because top teams rarely lose at home, and the number of observations by league is too small. Figure 4 summarizes our main findings.

Table 7: Regressions indicating home-team bias

## 5.7 Alternative influential (top-ranked) team definitions and results

There are several alternative measures to ranking used.

**Estimated squad value** of each team at the start of the season. This is based on adding up individual player values for squads.

**Top 20 in revenues over 10 years** is a very simple metric could be considering the top 20

Figure 4: Estimated regression coefficients by league

teams that have generated the most revenue in the last 10 years as favorite of the matches they are playing, unless these top teams play against each other. The latter matches, along with those involving no top team, are labelled as matches with no clear favorite. It is a binary variable by design.

Regarding financial power, data was collected from [this](#) Wikipedia page. The top 20 teams are the following: Arsenal, Chelsea, Liverpool, Manchester City, Manchester United, Tottenham from England; Lyon, Marseille, Paris Saint-Germain from France; Bayern Munich, Borussia Dortmund, Hamburg, Schalke 04 from Germany; AC Milan, Inter Milan, Juventus, Roma from Italy; Atletico Madrid, Barcelona, Real Madrid from Spain.

**Points** in the league is the end-of-season number of points per team, the higher the better. Points are typically between 20 and 100. The ranking in the actual year is best predictor of perceived quality, but an alternative is the past year value.

**Pre-match odds.** To measure quality, we use the pre-match odds, cleaned from incorporated home advantage. We achieve this by estimating  $\widehat{Odds}_{ij} = \alpha + \beta Home_{ij} + \epsilon_{ij}$  where  $Home_{ij}$  is an indicator whether team  $i$  is the home team in match  $j$ . Then, for each match  $j$  with a one-goal difference at 90:00, we take the home-away difference between the estimated  $\epsilon_{ij}$ s. This metric is used only for difference between teams.

**Elo ranking** is a ranking based on the cumulative quality of opponents. In our estimation, values are demeaned at the league level.

Below, we reproduced key results with alternative influential team definitions.

[To be added.]
